

The effect of climate change in experimental archaeology.

By David Freeman
December 2018

When you plan your experiment, how many of you think about the climate, and whether it matches the period that your experiment is based in? There are many factors that may influence the results, depending on the type of experiment. You need to consider parameters such as; humidity, ambient temperature, how effective your clothes are, burning the right firewood, keeping a shelter warm, or the quality of the grass that your animals are living on.

With the climate change we are going through, a lot of thought needs to be put into the experiment in order to match the pre-historical/historical conditions you are trying to emulate.

I am already coming up against the effects, in the construction of prehistoric buildings.

In the last fourteen years I have had the privilege of researching, designing, and constructing, a complete generation of prehistoric buildings at Butser Ancient Farm.

In 1970 when the 'Butser Ancient Farm Project' was first mooted, it was decided the climate in the 70's was deemed to be comparable with that of the late Iron Age. Therefore, in 1972 when Peter Reynolds became the first director of the farm, this limitation was kept in mind. This influenced the production of timber, the growth of grass, the crops and the growing season.

For the last 14 years, I have maintained this idea as a steering mechanism as I've been experimenting with the new generation of buildings at the farm. However in the last 3 or 4 years there has been a distinct change in the way that the buildings have been behaving. Two of the changes are in available materials, the production of timber, particularly in the process of coppicing (the wood is not developing the same way that it was). The timber used in the building of the houses is now growing faster and is therefore not as stable. The thatch used on the buildings is bought in, i.e. not produced on farm. However there has been a noticeable change in quality of straw in particular. The thatch is a poorer quality, and is proving to be less reliable in providing a waterproof coating. The implications in the change of material means that it is not as easy to build an accurate house specifically to late Iron Age.

A major factor in the last 2 years is that there has been a greater insect infestation in the buildings. Any house without a fire in the hearth is becoming a target (or lunch, depending on how you look at it) and they are eating away at the framework of the building, purlins in the lower roof seem to be hit the hardest, with hazel being targeted in particular.

The conclusion? Long term, it is becoming harder to estimate the lifespan of a building, and it will affect the frequency of repairs. Monitoring is going to be important, to help spot the changes. Perhaps we have got to face the fact that as far as buildings are concerned, the iron age is no longer the period to be explored?
